

Optical Module Encoding Principle

Overview

An optical encoder is a type of motion sensing device that uses light shone through a coded disk to track the movement of a shaft. The encoder provides feedback based on the interruption of light. The graphic below outlines the basic construction of an optical incremental rotary. Optical encoders, built around diffraction gratings and photoelectric detection, convert rotary or linear motion into electrical signals. It consists of three primary components: a light source (typically an LED or laser), a rotating or linear code disk with precisely etched patterns, and, as an essential component of optical fiber communication, optical modules are optoelectronic devices that facilitate the conversion between optical and electrical signals during the transmission process. Its primary function is converting physical movement, whether rotation or straight-line travel, into a usable digital electronic signal.
